

Can Dark Matter be Ultra Heavy Particles ?

H. Ziaeeepour

The detection of High Energy Cosmic Rays (HECR) with energies around and beyond GZK expected cutoff has introduced the idea of existence of a decaying Ultra Heavy Dark Matter (UHDM). If this type of particles make a substantial part of the CDM, their decay can have important implications for evolution of the large structures and high energy backgrounds. Here we present preliminary results of numerical solution of Boltzmann equations in presence of a decaying CDM. The evolution of baryons and photons energy are calculated. We find that in a homogeneous universe, UHDM can not have a large contribution to the CDM. However, this hypothesis can probably survive if one takes into account the clumpiness of the matter in the Universe.

1 Motivations and Evidences for a Very Heavy Dark Matter

One of the recently raised and yet unexplained issues in Particle Physics is the observation of Ultra High Energy Cosmic Rays (UHECRs)(For a review see ²⁸). The source of these particles can not be in a distance larger than $30 - 50 Mpc$, otherwise, interaction with CMBR and IR photons considerably reduces the energy of the primary particles ¹¹. This phenomena should produce a steep cutoff (GZK cutoff) in the spectrum of CRs at energies around $\sim 10^{18} eV$ to $10^{20} eV$. Observation shows a local minimum in the spectrum around these energies, but unexpectedly it rises again at higher energies. In fact the spectrum is compatible with two distinct class of sources, one for energies less than $\sim 10^{18} eV$, and the other for higher energies. It is very difficult to detect the composition of UHECR primaries. It seems however that the data is more compatible with proton or neutrino like primaries ¹³.

No candidate source has been observed in the direction of UHECRs in a distance permitted by GZK cutoff. N. Hayashida *et al.* ¹⁵ reports a small excess of $\sim 4\%$ for UHECRs with energies $\sim 10^{18} eV$ in the direction of the Galactic Center and Cygnus region. However, it is shown ¹⁰ that there is not any correlation between observed events and any of individual galaxies in the $50 Mpc$ radius for events with energies $> 10^{18} eV$.

Standard production mechanism of UHECRs is the acceleratation of charged particles in the shock waves of AGNs, SNs, or in-falling gas in rich clusters. The main condition for these objects to be able to produce the observed spectrum of UHECRs is the existence of relatively strong magnetic field with large

coherence length. The secondary acceleration of charged particles by remnant of old SNs can accelerate protons up to $\sim 10^{15}eV$ and iron to $\sim 10^{18}eV$ ²⁷. Models for proton acceleration in AGNs can produce UHECRs up to energies $\sim 10^{20}eV$ ²³ with a marginal maximum energy of $4 \times 10^{21}eV$ ⁴. They also predict a change of composition from iron to proton. However, the uncertainty on jet density, coherence length of the magnetic field in hot spots and large distance to the candidate sources incompatible with energy loss due to interaction with CMB, make these sources marginal candidates.

Gamma Ray Bursts (GBR) also have been proposed as the candidate source for UHECRs²⁰. If UHECRs are produced in a relativistic shock wave, one expect to observe after-glows of this process in lower energies (like GBRs). Attempts to find an excess of TeV range γ -Rays in the direction of observed UHECR events have failed⁷. One more argument against an acceleration source for UHECRs is that one expects to observe a bunch of UHECRs at least for the most nearby sources as it is the case for GRB. No such event has been yet observed.

Another possible class of sources for these events is the decay of a very heavy elementary particle with a GUT-scale mass³. These particles can be either long life very heavy particles, or short life particles produced from the decay of topological defects. In the latter case, the heavy particles decay in their turn to ordinary particles and make the observed UHECRs. There is a number of mechanisms which can produce long life ultra heavy particles in the early universe. At the end of an inflationary epoch, the parametric resonance of inflaton field oscillation can produce very heavy particles with masses larger than inflaton mass itself¹⁸. In super-symmetric models where SUSY breaking in the hidden sector is communicated to the observable sector by gauge fields, the existence of a global symmetry can lead to stability or long life of lightest particle. The lightest messenger gauge field get also a large mass and under some symmetry conditions can have a long life²². Vacuum fluctuation of a background field coupled to the gravitation also can produce very heavy particles with $\Omega_X \approx 1$ for a range of inflaton mass and self coupling⁸. This makes these particles a very good candidates for Dark Matter (DM). The unitarity constraint on the mass of DM particles¹² can be turned over if they have never been thermalized. The condition of a long life time for a very heavy particle can be fulfilled if it has some discrete gauge symmetry¹⁴. The possibility that topological defects be the source of UHECRs has been also studied extensively¹⁶. Some years ago, there was a lot of hopes and attempts to prove that topological defects can be the seed of LSS and CMB fluctuations (see⁶ for a review). However, the results of comparison between simulations and observed power spectrum of LSS and CMB anisotropy practically rules out

this possibility².

By contrast, as mentioned above, some models can produce a CDM totally composed of ultra heavy particles⁸. Their decay can have important implication on the evolution of LSS. Remnants contribute to the total amount of baryonic matter in the universe mostly as a non-thermalized hot component. Another important implication is the production of large amount of high energy backgrounds. This can be used as a test for verification of this hypothesis. In this work, we calculate the opacity of the universe for remnants with highest energies and the evolution of their energy spectrum. We compare expected flux if CDM is UHDM, with observations.

2 Model

We assume that the X particles are neutral bosons with a mass $m_X = 10^{24}eV$ and a life time $\tau = 1.2^{10}yr$. If the decay of these particles looks like the decay of Z^0 , theoretical and experimental arguments show that leptonic and hadronic channels have a branching ratio of $\sim 1/3 - 2/3$. Other channels have a negligible contribution. As the dominant channel is the hadronic one and the leptonic channel makes very soon a cascade, here we only consider this mode of decay. It is very likely that X particles don't decay directly to known particles. This leads to softening of the energy spectrum. For simulation of hadronization, we consider the hadronization of two gluon jets. Experimental observation as well as MLLA (Modified Leading Logarithm Approximation)²¹, LPHD (Local Parton-Hadron Duality)^(17 and references therein) and string hadronization model¹ obtain a softer spectrum with higher multiplicity for gluon jets than for quark jets. This is probably more convenient for the decay of X particles.

We use PYTHIA program²⁵ for jet hadronization. This program, like many other available ones, can not properly simulate ultra high energy events, not only because we don't know the exact physics at $10^{16}GeV$ scale, but also because of programming limits. For this reason, we had to extrapolate simulation results from lower energies. Fig.1 shows as an example, the photon multiplicity for hadronization of a pair of gluon jets. At energies larger than $10^{12}eV$, the multiplicity per $\log(E) \sim y$ (rapidity) is roughly constant. The same behavior exists for other species. It is the result of KNO scaling predicted by MLLA. We use this property to extrapolate the multiplicity spectrum to invariant CM mass of $10^{24}eV$. It should be mentioned that at high energies, one expects that KNO scaling be violated. The fact that in Fig.1 we don't see this effect shows that at high energies, the results of simulation programs can be uncertain. We think that various parameterizations of hadronic spectrum

Figure 1: Photon multiplicity in hadronization of a pair of gluon jets with CM energies from $10^{12}eV$ to $10^{24}eV$.

also suffer from the same problem, simply because they have been fitted to low energy models or observations. In this respect, simulations are probably more close to reality because they take into account more non-perturbative effects. In the simulation, we assume that all particles except $e^\pm, p^\pm, \nu, \bar{\nu}$ & γ will decay. The mean energy contribution of the stable species is as the following: 13% $e^\pm$, 25% $p^\pm$, 36% ν & $\bar{\nu}$ & 25% γ . More than 99% of the total energy belongs to the particles with energies higher than $10^{20}eV$. If baryogenesis happens in GUT scale, we expect an excess of baryons over their anti-particles. We assume a positive baryonic number and a null leptonic number. This results to an excess of e^- and p^+ over e^+ and p^- (to keep the universe electrically neutral), and $\bar{\nu}$ over ν . For simplifying our simulation, we assume that all ν 's are ν_e and massless. It is interesting to note that ν 's have the largest contribution to the total decay energy.

The decay of a very heavy particle has two implications: Energy dissipation of the remnant in one hand heats the ordinary (visible) matter in the Universe and on the other hand it contributes itself to the yield of the visible matter. To calculate the spectrum of the remnant, one has to solve the complete Einstein-Boltzmann equations. Even in the case of linearized equations, the presence of interactions makes this system of equations non-linear and coupled. Specially, in the case of UHECR energy dissipation, the problem is highly stiff in the sense that one has to treat 29 orders of magnitude in energy, from CMB energy to the mass of X particles. The numerical solution of these equations is under test²⁹. Here we discuss the results of a more simplified model. We consider a homogeneous universe and we neglect the production of high energy particles due to interaction of remnants with backgrounds. The reason behind this assumption,

Figure 2: Optical depth versus energy at different red-shift. Energies are particle energy at $z = 0$. Solid $z = 0.02$, long dashes $z = 0.1$, dash 3-dot $z = 0.5$, dash dot $z = 2$, dashed $z = 10$, dot $z = 50$.

apart from simplifying the model, is that we are only interested in comparing the predicted flux for very energetic particles $E > 10^{17} \text{eV}$ with observation, as we know that lower energies have other sources than presume UHDM and thus, they are not directly signals of these particles. We assume that particle energy completely dissipates and makes a high energy background. For γ and neutrinos, we assume that this background has a Gaussian distribution. For massive particles i.e $e^\pm$ and $p^\pm$, we assume that they have a fixed mean temperature. In one hand this simplification is motivated by the results of S. Lee in¹⁹ where propagation of UHECRs has been studied for a flat homogeneous universe. He considers also the effect of production of high energy particles from interaction of remnants with backgrounds and show that there is an increase of photon background at energies lower than $\sim 10^{14} \text{eV}$. On the other hand, there are numerous evidence of existence of a hot IGM, ICM (intra-cluster medium).

Figure 3: Energy Flux at $z = 0$ with 4 different γ backgrounds: Solid and dotted $E_{bg} = 10^{10}eV$, dashed and dash $E_{bg} = 10^6eV$, and respectively with and without radio background. Dots present observed flux. Only highest energies should be compared with observation.

Backgrounds else than remnants are BBN baryons, primordial neutrinos and CMB and star light. We use models developed by Salamon & Stecker²⁴ and by Vernet & Valls-Gabaud²⁶ respectively for IR and visible and for UV backgrounds. We assume $\Omega_m = 0.3$ and $\Omega_\Lambda = 0.7$.

As expected, the optical depth depends on the temperature assumed for the remnant background. Neutrinos temperature is assumed to be $10^{12}eV$. The reason for this choice is that at lower energies their cross-section is very small. Remnant photons have significant role on the opacity of high energy particles. We studied following temperatures: 10^4eV , 10^5eV , 10^6eV and $10^{10}eV$. Each of these temperatures has its maximum effect for a range of remnant energies. Fig.2 shows as an example, the optical depth for $E_{bg}^\gamma = 10^6eV$. Reducing background energy increases the optical depth because the number of photons will increase.

Fig.3 shows the density of stable particles at $z = 0$. Irrespective of background photon energies, the expected flux of UHECRs at $z = 0$ from the model is much larger than observed flux. This result definitively rule out the existence of large contribution of UHDM in the CDM or its life time must be at least 4 order of magnitude larger than the age of the Universe (see also⁵). However, we believe

Figure 4: Optical depth of a clump with radius = $1Mpc$ and $\frac{\delta\rho}{\rho} = 200$ for $e^\pm$ and γ solid line, $p^\pm$ dash dot, ν dash 3-dot and $\bar{\nu}$ long dashes.

that our model is too simplified. The Universe is far from having a uniform distribution of matter. Dark Matter as well as baryonic matter is clumpy. The opacity for remnant is proportional to the density of the background. Fig.4 shows the optical depth of a clump with a mean over-density of $\frac{\delta\rho}{\rho} = 200$ and a radius of $1Mpc$. Apart from ν s, all other high energy species dissipate their energies in the clump. This results to a large reduction of expected flux on the Earth and can probably survive the UHDM model. More results about the effect of clumpiness on the UHECRs will be reported elsewhere.

I am grateful of J. Vernet and D. Valls-Gabaud for providing me with the results of their UV background model.
